Rosenthal, Rosnow, and Rubin have changed that, with their discussion of contrast analysis and effect sizes. Plus side: The text gives in depth coverage on the design and conduct of contrast analysis, testing particular theoretical predictions using more general data sets. EFFECT SIZES AND SIGNIFICANCE LEVELS The basic lesson so far is that contrasts usually give us greater substantive in-terpretation of research results and greater power for tests of significance. Another advantage of contrasts is that effect sizes can often be easily computed from data in published reports as well as from raw data.

The simplest contrasts consist of comparisons of two samples (e.g., based on the independent t statistic). Useful effect-size indices in this situation are members of the g family (e.g., Hedges's g and Cohen's d) and the Pearson r.

Contrasts and Correlations in Effect-Size Estimation ...
The Contrast Correlation As noted, when the contrast is a simple comparison between two independent groups, the effect-size correlation (hereafter denoted as reffect size) is the point-biserial correlation between each subject’s group membership (coded as 0 or 1) and the score on a continuous variable.

Contrasts and Correlations in Effect-Size Estimation
Your effect sizes for your pairwise contrasts would be derived from the test that is associated with the effect. For example, if you are doing a pairwise t-test comparing cells of your design, then your effect sizes would be derived from each of those pairwise t-tests (using whatever error term you select for those pairwise tests).

Therefore, a significant p-value tells us that an intervention works, whereas an effect size tells us how much it works. It can be argued that emphasizing the size of effect promotes a more scientific approach, as unlike significance tests, effect size is independent of sample size.

For pairwise contrasts we can use Cohen’s measure of effect size, namely. which can be implemented using Hodges measure of effect size, namely. This can be extended to the comparison of more complicated contrasts. E.g. for the null hypothesis H 0: we can use the following value for g. The interpretation of g is the same as for a comparison of two means. This measure of effect size can be extended to the omnibus ANOVA.

The contrast effect is a cognitive bias that distorts our perception of something when we compare it to something else, by enhancing the differences between them. This comparison can be either explicit or implicit, simultaneous or at separate points in time, and can apply to various traits, ranging from physical qualities, such as color and taste, to more abstract qualities, such as price and ...

Consistent with long-standing best-practice recommendations, bootES computes effect sizes only for 1-degree-of-freedom (df) effects, also known as contrasts or focused comparisons (see, e.g., Rosenthal & Rosnow, 1991, pp. 467–469, 486).

You need to fill in the desired contrasts directly in the output (e.g. for Example 4 you need to fill in the range O32:O35 in Figure 7 with the contrasts you desire). When you click on OK, the output from this tool is displayed (as in Figure 8). The fields relating to effect size are explained in Effect Size for ANOVA.
